## Anti-stokes emission from gold nanorods

Figure S1 shows the energy-momentum representation of the photoluminescence processes in gold nanorods.

Figure S1: Schematic of the anti-Stokes luminescence process from a single gold nanorod in the energy-momentum space. After excitation with monochromatic light of energy  $\hbar\omega_L$ , a collective oscillation of electrons is generated, i.e. a surface plasmon (SPR). Once the coherence is lost (dephasing time  $\sim$ fs), the state can be described as an electron-hole pair. Then, three scenarios are possible: electron and hole may recombine radiatively after one or more interactions with the thermal baths of lattice phonons and charge carrier thermal excitations: i) if the energy difference between electron and hole states is lower than the initial one after excitation we obtain Stokes emission upon a radiative recombination; ii) if electron and hole transiently increase their energy difference at the bath's expense before recombining radiatively, we observe anti-Stokes emission; iii) if electron and hole recombine non radiatively, their energy difference is transferred to the baths and no photon is emitted. The latter process is the most probable one.

## Experimental setup

The experimental setup consisted on a home-made confocal microscope, schematically shown in figure S2, similar to the one presented before.<sup>1</sup> It allows the detection of individual nanorods in the sample and the measurement of their photoluminescence spectra.

Additionally, the temperature of the sample can be controlled with a special holder that allows water flow, a heater and a thermocouple to measure the temperature of the sample.

Figure S2: Scheme of the experimental setup. The sample has individual gold nanorods on glass. BS: beam splitter. NF: notch filter to remove excitation light and detect Stokes and anti-Stokes photoluminescence. L: lens. FM: flipper mirror. SPEC: spectrometer. APD: avalanche photodiode.

## Gold Nanorod temperature calculations

Figure S3: Calculated temperature for a 21 nm  $\times$  50 nm nanorod under different excitation intensities. The full line is the result of the simple model while the dots are the calculated values using Comsol. The circles were obtained with the temperature-dependent heat conductivity and the diamonds with a constant value of  $0.61 \text{ W}(\text{m} \cdot \text{K})^{-1}$ .

Throughout the main text the temperature measured with the anti-Stokes emission is compared to the calculated temperature using a simple heat diffusion equation. For spheres, assuming an infinite thermal conductivity of the metal, the temperature increase is given by

$$\Delta T(P) = \frac{P}{4\pi k_{\text{water}} R} \quad (1)$$

where  $P$  is the dissipated power,  $k_{\text{water}}$  is the heat conductivity of water and  $R$  is the radius of the particle. The dissipated power can be easily derived from the cross section of the particle at a given wavelength and the intensity of the focused laser beam. For nanorods we assumed an equivalent sphere with radius such that the total rod area is preserved.

Figure S3 shows the difference between the results from the equation (full line) and a finite element method calculation using Comsol (dots) for a nanorod of length 50 nm and diameter 21 nm. The cross section and dissipated power were kept the same. The blue circles are the results given by using the built-in material properties of water, i.e. a thermal conductivity that depends on temperature. The diamonds are the results when the thermal conductivity

---

is fixed to  $0.61 \text{ W}(\text{m} \cdot \text{K})^{-1}$ . The difference is accentuated at higher temperatures.

## Luminescence power dependence

Figure S4: Stokes and anti-Stokes integrated emission as a function of excitation power. The linear fit in logarithmic scale has a slope of 0.88 and 1.20 respectively, ensuring the 1-photon nature of both kinds of emission.

Figure S4 shows the intensity of the Stokes (red) and anti-Stokes (blue) emission for several excitation powers. In both cases the linear fit in logarithmic scale has a slope close to 1, being 0.88 for the Stokes and 1.20 for the anti-Stokes, confirming that both types of emission are single-photon processes. We speculate that the anti-Stokes has a lower slope due to dependence on  $T$  in the equation 2 in the main text. The behavior is independent of the plasmon resonance position. It is important to note that the excitation intensity cannot be increased much beyond what is shown because nanorods would start reshaping towards more spherical shapes at higher laser powers.
